Keywords: Embodiment, Symbols, Situated Reason, Surrogate Situations, Mole Cricket, Singing Burrows, Language, and Attention.

Abstract

What do linguistic symbols do for minds like ours, and how (if at all) can basic embodied, dynamical and situated approaches do justice to high-level human thought and reason? These two questions are best addressed together, since our answers to the first may inform the second.

The key move in 'scaling-up' simple embodied cognitive science is, I argue, to take very seriously the potent role of human-built structures in transforming the spaces of human learning and reason. In particular, in this paper I look at a range of cases involving what I dub 'surrogate situations'. Here, we actively create restricted artificial environments that allow us to deploy basic perception-action-reason routines in the absence of their proper objects. Examples include the use of real-world models, diagrams and other concrete external symbols to support dense looping interactions with a variety of stable external structures that stand in for the absent states of affairs.

Language itself, I shall finally suggest, is the most potent and fundamental form of such surrogacy. Words are both cheap stand-ins for gross behavioral outcomes, and the concrete objects that structure new spaces for basic forms of learning and reason. A good hard look at surrogate situatedness thus turns the standard skeptical challenge on its head. But it raises important questions concerning what really matters about these new approaches, and it helps focus what I see as the major challenge for the future: how, in detail, to conceptualize the role of symbols (both internal and external) in dynamical cognitive processes.

Introduction

Dynamics, embodiment and situatedness are widely advertised as having radical implications for the sciences of the mind [43, 36, 23, 41, 42, 39]. Sceptics, such as Clark and Toribio [12] have pointed out that the most radical such implications seem confined to a small class of cases. These are cases involving the dense, time-pressured, coupled unfolding of a behavior, typically regulated by an ongoing perceptual link with some external goings-on. For example, reaching for a visually presented object, returning a tennis serve, and so on. But such cases, the skeptic insists, are cognitively marginal. The proper explanatory targets for the sciences of genuinely mental activity, they suggest, involve thought and reason that targets distal, absent, highly abstract, or even impossible, states of affairs. Good explanatory frameworks for the highly coupled cases look less promising, it is claimed, in these more rarified arenas.

I examine this argument and find it less compelling than I once believed. In particular, it is flawed by a conflation of two distinct properties. The first is the property of disengagement (reason operating in the absence of it's ultimate target, as when we think of that which is not close to hand). The second is the property of de-contextualization (reason operating without the kinds of dense

perceptually-saturated local couplings that most obviously reward treatment in dynamical and situated terms). I shall argue that high-level reason is local and contextualized even when (and indeed most strongly when) it is disengaged. The most obvious examples being when we use real-world models, diagrams and other concrete external symbols to create conditions of (what I shall call) surrogate situatedness. In such cases, we reason about what is not at hand by means of dense looping interactions with a variety of stable external structures that stand in for absent states of affairs.

Language itself, I shall finally suggest, is the most potent and fundamental form of such surrogacy. Words are both cheap stand-ins for gross behavioral outcomes, and the concrete objects that structure new spaces for basic forms of learning and reason. Language is thus conceived as primarily a form of environmental structuring rather than as an information stream requiring translation into and out of various inner codes.

A good hard look at surrogate situatedness thus turns the standard skeptical challenge on its head. But it raises important questions concerning what really matters about these new approaches (in particular, it undermines a certain view of the role of simple temporal constraints). And it helps focus what I see as the major challenge for the future, viz, how, in detail, to conceptualize the role of symbols (both internal and external) in cognitive processes.

I.   From Finger-Wiggling to Foreign Policy.

It seems fair to say that most (though not all) of the really compelling accounts to emerge from the stables of dynamical and embodied cognitive science depict cases of densely coupled unfolding. By this I simply mean that they involve the

use of a percepuo-motor routine whose operation exploits the continuing presence of some tangible target. The simplest example might be a wall-following or phototropic robot. But more impressive demonstrations include the robot cricket that identifies and locomotes towards towards the call of its mate [44], the account of how baseball outfielders run to catch a fly ball [28], the work on hopping robots [31], the detailed dynamical model of the production of rhythmic finger motions (the account of co-ordinated index finger wiggling nicely reviewed in [23]), and the recent explosion of work on animate vision, just-in-time sensing, and the use of 'deictic pointers' [1] and robotics work reviewed in [30].

In cases such as these (and there are many others) we confront a characteristic mix of constraints and opportunities, that I'll label the 'basic signature'. The basic signature involves a task that requires the agent to keep track of a situation unfolding in some constraining (absolute) time-frame, so that real timing (not just sequence) is essential to success. And it involves the use, to accomplish the task, of body, motion and world as integral aspects of the problem-solution. For example, the use of head and eye motion and 'just-in-time' sensing to retrieve information from the visual scene, thus (as Rodney Brooks put it) 'using the world as its own best model'.

This signature mix of constraints and opportunities looks to be lacking in many cases of high-level human problem-solving. We can plan next year's family vacation, design a new 100 storey building, or sit down and think about equality, freedom and the negative impact of the 'war on terrorism'. In such cases we are forced to think and reason in the absence of the target situation. The vacation is not until next year. The building does not exist (and may even be impossible). Equality and freedom are not out there for simple perceptual re-encounter as and when required. Instead, we seem forced into a mode of 'off-line

reasoning'.. The tools, principles and strategies that work so well for co-ordinated finger-wiggling and its ilk may falter, it is feared, in the face of such new demands and challenges.

There are two standard replies to this worry. The first argues that any hard-and-fast on-line/off-line distinction is itself unclear and potentially misleading. Rather, in just about all cases, we find elements of each and a constant seamless integration of the two. The need to integrate real-time action with ongoing planning and reason is itself, it is argued, a reason to prefer a unified dynamical approach that treats perception, reason and action in essentially the same terms. For a powerful version of this argument, see [37]. Randy Beer's [3] experiments (and more recently, those of Slocum [33] with 'minimally cognitive agents' may also be seen as partial support for this class of response.

The second response is to argue that even imagination-based, problem-situation decoupled reason is fully continuous with the other cases, because our imaginative routines are *themselves* body-based, exploit egocentric co-ordinate spaces, (re)deploy the same perceptuo-action oriented inner states, and so on. For various versions of this, see [37, 27, 2, 24].

Both these responses are useful and important. But there is a third move available that may, I think, prove more fundamental than either standard reply. To introduce it, let's take a brief detour into the surprising acoustic world of the singing cricket.

2. Singing Burrows

Crickets sing to attract mates of their own species, and where these songs are concerned, louder is generally better. A louder song reaches more potential

mates, and is typically deemed more attractive than any weaker-sounding competitor. The onboard mechanism responsible for producing the sound is a patch of flexible wing membrane, known as the harp, that is pulled taut and struck using a kind of tooth and peg arrangement. The overall process is termed 'stridulation'.

There is, however, a problem. Crickets are quite small creatures, and their onboard harps are tiny relative to the wavelength of their carrier tones. This is very inefficient in a free (unobstructed) sound field, and much of their muscle energy is wasted, turned not into sound but lost doing capacitive and inertial work. The typical efficiency achieved by many cricket species is a paltry 1.5 to 2% (of expended pinging energy turned into sound). The biologist J. Scott Turner [40] offers a detailed and compelling analysis of the strategies used, by a few cricket species, to make more efficient use of this muscle energy.

One strategy is to first bite a hole in a leaf, and then to position the harp over the hole which then acts as a baffle, making the sound 2 to 3 times louder and allowing it to project to a volume 40 times greater. Starting with the basic physics of sound emission, however, Turner shows that the ideal (but impossible) solution would be to enclose the sound emitter in an infinite horn. This would preclude all loss of energy to inertial and capacitive work (you can't accelerate an infinite mass of air and it can't store energy to do other work), forcing all the energy to turn into sound. Infinite horns, like true Universal Turing Machines, do not exist. But a good approximation is the so-called Klipsch horn. This is a horn that flares like a trumpet (aka an exponential horn) with a capacious end bulb (corresponding to the musician's mouth cavity) connected by a restricted opening (such as the lips or a reed) to the horn. This set-up allows the air inside the horn to be turned back to help drive the emitter via a kind of turbo-charging called 'loading the horn', and it allows the trapped air to resonate at a frequency related to the length of the horn. In essence, the sound field is obstructed in a

good way, vastly reducing the amount of energy lost to capacitive and inertial work.

Amazingly, several species of mole cricket (especially *Scapteriscus acletus*, and *Gryllotalpa vinae*) exploit physically perfect Klipsch horns as a means of efficient sound production. These crickets tweak their own burrow-building activities so that one tunnel takes the form of a large bulb, while another flares like an exponential horn. The cricket sits in a narrow constriction between these two animal-built structures and stridulates (sings). In this way the burrow acts as a 'tuned impedance transformer' carefully fitted to the specific carrier wave of the species. Sometimes, a single cricket will sit at the intersection of two such tunnel/bulb arrangements. With the ground itself acting as a very large (near-infinite) baffle, and the boost of a double exponential horn, these crickets obtain an almost unimaginable increase in acoustic efficiency. In the case of *Gryllotalpa vinae* a full 34% of the muscle power used for stridulation is now turned into sound . Compare this to a maximum of 5% for an unaided field cricket, though even this is admirable since high end audio loudspeakers, as Turner points out, manage only a meager conversion efficiency of about 2% (of power into sound). The souped-up mole cricket, however, produces one of the loudest sounds made by any animal. The sound can be heard at 600 metres while the ground itself vibrates for a 20 cm radius.

Turner argues that the mole cricket's burrows, like several other animal-built structures that he considers in the same mongraph, are functionally equivalent to the possession of a near-perfect physiological sound-emitting organ. Turner's larger goal, in fact, is to argue that for many biological purposes such animal-built structures should be counted as proper parts of the animal's physiology and thus to breach what he describes as "the essentially arbitrary boundary between organisms and the environment" [40].

Notice, however, a clear difference in evolutionary costs. To create the singing burrows, all the genes need to encode is a strategy for feedback-tuned excavation and tunneling. The male Mole cricket digs, settles into the constriction and emits a special kind of chirp (a test chirp). He then repeatedly alters the size and shape of the burrow until the right resonant frequency is heard. Finding this feedback-driven behavioral strategy and loading it into the genome, Turner argues, was plausibly much faster and cheaper than making the long sequence of small changes needed to install a Klipsch horn as a biological-physiological organ.

The Mole cricket scenario is simply a comparative springboard: a dramatic device to bring home the quite staggering transformative potential of our own 'Cognitive Singing Burrows'. The dramatic device is helpful because, despite our familiarity with the notion of human technologies as 'cognition amplifiers' [18, 14], the ubiquitous presence of these amplifiers (pen, paper, models, words, numbers, blueprints, compasses) often blinds us to the depth and importance of their role in 'distinctively human thought'. By the close of the present treatment we will also see many fundamental respects in which our own 'Cognitive Singing Burrows' far exceed (in the cognitive realm) the transformative impact of the simple acoustic Singing Burrow. We thus better appreciate the deeply hybrid (biological and artifactual) nature of the human mind.

To anticipate one such case, notice immediately that certain Cognitive Singing Burrows (such as the use of external media to store new ideas) take even more pressure off the genome than was true in the acoustic case. Now, even the *strategies needed* to build specific external structures (such as paper-mills and factories) can be preserved and transmitted by non-biological means! Moreover (and this is especially important in the present context), many of our Cognitive Singing Burrows function precisely so as to relax specific constraints on real-

time, engaged and embodied response (see section 3 below). The question of whether human cognition is best understood as "embodied all the way up" is thus revealed as importantly ambiguous, as are claims of 'seamless continuity' between basic animal and infant minds and our own.

3. Surrogate Situations

The most basic form of 'Cognitive Singing Burrow', I want to argue, is the use of 'surrogate situations'. By a surrogate situation I mean any kind of real-world structure that is used to stand in for, or take the place of, some aspect of some target situation. By a target situation I mean an actual, possible, or at least superficially possible, real-world event or structure that is the ultimate object of my cognitive endevour. For example, suppose I use a dotted line, or a small stick, to indicate, on a rough drawing, the proposed location of a strut on a barn door that I am about to build. The target situation is the (as yet non-existent) door and the surrogate situation is the context provided by the drawing (and the stick, if I am using one).

Real-world processes of design, as Henrik Gedenryd [17] has argued in great detail, are marked by the use of multiple complementary uses of surrogate situations. Examining cases as diverse as designing a building or laying out a magazine cover, Gedenryd details the different uses sketches, prototypes, thumbnails, storyboards and scenarios, to name but a few. What these all have in common, of course, is that they allow human reason to be disengaged (to reach out to that which is absent or distal or otherwise unavailable) while at the same time providing a concrete arena in which to deploy perceptuo-motor routines of a fundamentally world-engaging kind. In such cases, human reason is, we may say, disengaged but not disembodied.

9

While it is no doubt obvious enough that we often rely on such a strategy, its pervasiveness, variety and importance is easily overlooked. Considered in the light of the typical worries about 'scaling up' the embodied approach to higher human cognition (section 1 above), such tactics are revealing indeed. The mock-ups (etc) serve no primary purpose other than that of allowing human reason to get a grip on what might otherwise prove elusive or impossible to hold in mind. Any given project will often rely on the use of multiple kinds of surrogate situation, each of which highlights or makes available some specific dimension of what Gedenryd calls 'the future situation of use'. In this way, surrogate situations are not simply miniature version of the real thing. Rather, they are selected so as to allow us to engage specific, and often quite abstract, aspects of the future situation of use. For example, a 4 ft eye-level simulation of a walk-through a new living and teaching space may be selected to address the need to develop a 'safe and inspiring environment for 4-6 year olds' [17]. In a similar fashion, page layout designers use very rough thumbnails to work out potential relations between graphic and textual objects, and are explicitly counseled to omit distracting detail.

In fact, despite certain recent educational trends that over-emphasize the creation of rich and realistic teaching contexts, it may well be that our fluency with surrogate situations depends, to a certain extent, on actively keeping the level of non-essential detail quite low. Judy Deloache, in a 1991 [15] study of symbolic functioning in very young children, found that the more realistic the surrogate situation, the harder it became for children to use it as a tool to understand a target problem. In a series of experiments, Deloache and her co-workers had children (2 –3 years old) watch as a model toy is hidden under a model piece of furniture. They are then told that the real toy is hidden in the same place in the real room. Despite ensuring that the children understood the instructions, the experimenters found that more realistic models actually degraded performance.

For example, children performed better when shown a 2D picture rather than a 3D scale model. And with the scale model, performance could be improved by placing it behind glass, thus impeding full physical interaction. Deloache suggests this is because as the mock-ups physical properties become more salient, and afford a wider range of interactions, the child's ability to use it as a symbol decreases. Related findings in adult performance include Markman and Gentner's [26] demonstration that grasp of abstract relations improves when the richness of the representation of the related objects is decreased, and Goldstone and Sakamoto's [19] demonstration that transfer of learning of abstract principles is often better when concrete details (and hence many superficial similarities) are surpressed in the original learning situation. One important lesson is thus that surrogate situations should be purpose-built to serve specific cognitive needs, and that any pre-theoretical commitment to maximal detail and realism is premature and may prove counter-productive.

Nonetheless, the fact that the surrogate situation provides SOME leverage for real-world action and intervention is crucial. In cases such as we have considered, the one thing the agent CANNOT do is to 'use the world as its own best model'. A non-existent building cannot act as its own best model, nor can a (merely) proposed route for a new road. Instead, in such cases, the agent must *let a model serve as its own best micro- world.* In so doing, she creates an arena in which many basic perceptuo-motor strategies (such as just-in-time sensing and binding) can be re-deployed, while at the same time constraining the kinds of thing that can and cannot be done and relaxing some of the most potent temporal constraints on normal world-engaged thought and action.

Much attention has been paid in the literature to the way good models, aids and mock-ups constrain action in productive ways (see eg work on graphical representations, such as [32, 13]. But equally important, though less noticed and

much harder to study, is the way such stand-ins alter and relax the temporal constraints on ordinary performance. Many of the classic cases of environmentally coupled perceptuo-motor action cited by dynamicists involve non-negotiable temporal restrictions: the tennis player must deal with a serve whose speed is determined by the opponent, the diving plover must penetrate the water while catching the fish, and the finger-wigglers must attain a certain speed of rhythmic motion. By contrast, routines applied to a model or mock-up seem relatively unconstrained by fine demands of timing. It really doesn't matter precisely how fast I move the model car into position, or how slowly I draw the lines in the sand describing a new football strategy. In one whole, and very important, class of cases, I actively create, as I go along, the very structures to which I then respond. I am here thinking of cases where I create my own model or mock-up, by writing symbols on a page or laying items out in front of me. In these cases, the agent is in charge of the temporal generation of the items that then structure and guide her own problem-solving. Evidently, there is much scope in such cases for an agent to time the production of new symbols or stand-ins in ways that are maximally conducive to her own success.

It is possible (though this is sheer speculation) that this temporal relaxation allowed us to begin to deploy a phylogenetically more recent set of neural cognitive strategies: ones that make richer contact with episodic memory systems and explicit stored knowledge, and are known to be major players in time-delayed as well as imagination-based responses. We have learnt, for example, that time-delayed and imagination-based responses, at least in visual processing, depend on distinctive activity in the so-called 'ventral visual processing stream' [29, 9]. Surrogate situations may thus provide a kind of evolutionary and developmental half-way house between fully 'off-line' imaginative modes of thought and reason and the more time-constrained domains of normal real-world response.

In sum, there exist clear qualitative differences between surrogate situations and normal situations, both in terms of content (the surrogates profit from idealization, abstraction and the omission of much concrete detail) and in terms of timing (the surrogates relax. These differences may have favored the use of novel neural and cognitive problem-solving strategies.

4. Words as Anchors in the Sea of Thought.

Words and symbols, whether spoken or written, are human-built structures, that (like the Mole Cricket's burrows) alter and amplify our powers of thought and reason. By treating words and symbols as cognition-transforming elements of external scaffolding, we open up new and productive ways of accommodating linguaform reason in a broadly embodied, dynamical framework.

In a fascinating recent study, Hermer-Vazquez, Spelke, and Katsnelson [22] speculate that knowledge of words may enable us to combine otherwise encapsulated mental resources into unified bodies of knowledge. More specifically, they claim that:

"Humans' flexible spatial memory depends on the ability to combine diverse information sources rapidly into unitary representations and that…in turn, depends on natural language" [22].

Evidence for this claim comes from studies in which rats and pre-linguistic infants were shown the location of a toy or food in a room, then disoriented and left to try to find the desired item. The location was determinable by remembering cues concerning color, geometry, scent etc. But the rooms were designed so that the geometric cues (eg length of wall) were insufficient, and would yield an unambiguous result only when combined with other information

(eg scent or color of the wall). Rats, as Cheng [7] has shown, stick with the geometric information, searching randomly in each of the two geometrically indistinguishable sites. Yet the rats are capable of using other cues, such as color and scent, in other tasks. Cheng concluded that the rat uses an insulated geometric-information based module for the navigational task. Hermer and Spelke [20, 21] reproduced this pattern of results with prelinguistic infants, who likewise relied solely on the geometric information, despite the apparent availability of other cues. Yet adults and older children are easily capable of combining the various (geometric and non-geometric) cues to solve the problem. Success at combining the cues was not predicted by any measure of the children's intelligence or developmental stage except for the child's use of language. Children who were able to spontaneously conjoin spatial and (eg) color terms in their speech (who would describe something as, say, to the right of the long green wall) were able to solve the problem. Those not displaying this pattern of word use were unable to outperform the rats.

In an elegant 1999 study, Hermer-Vazquez [22] probed the possible role of language in this task by asking subjects to solve problems requiring the integration of geometric and non-geometric information while performing on of two other tasks. One task involved shadowing (repeating back) speech played over headphones. The other involved shadowing, with their hands, a rhythym played over the headphones. The working memory demands of the latter task were at least as heavy as those of the former. Subjects engaged in speech shadowing were unable to solve the integration-demanding problem, while those shadowing rhythym were unaffected. This result (alongside other experiments designed to control for possible other explanations) suggests to the researchers that language is actively involved in our ability to solve the problem requiring the integration of geometric and non-geometric information. More generally, it might even seem to suggest (see especially [6]) that language is the

unique medium (at least in humans) for the cross-modular integration of information. Perceptually encountered or recalled symbols and sentences act, according to Carruthers, like inner data structures, replete with slots and apt for genuine inner combinatoric action. This combinatoric action allows information from otherwise encapsulated modules to enter into a unified inner representation.This latter, rather sweeping, claim finds some support in a number of other studies discussed by Carruthers, including work on human mathematical abilities [35]. But I would like to offer an alternative interpretation, one that makes contact with my story about the use of surrogate situations.

In previous work [8, 10] I have discussed the role of tags and labels in making available forms of higher-order problem-solving. Chimps trained to use concrete tags (eg a plastic red square) for the relations of 'sameness' and 'difference' are able (unlike non-tag-trained chimps) to learn to solve second-order problems requiring them to judge of two pairs of objects whether the relations exhibited are themselves the same or different (for example, shown two identical cups and two identical shoes, the correct response is 'same' as the same relation (sameness) is exhibited within each pair). In attempting to explain these results, the authors of the original study [38] suggest that the early experience with the tags allows the chimps to imaginatively reduce the second order problem to a first order one. If the chimps, on encountering eg a pair of identical shoes, now call to mind an image of the tag (a red square), and if they do the same for the pair of identical cups, then all they need do to solve the harder problem is to judge that the two tag-images (two red squares) are the same. The higher-order problem is thus reduced to a lower-order one they are already able to solve.

Here, the skills acquired by practice using concrete symbolic objects (the plastic tags) seem to allow the chimps to perceive the scene in a new way. The effect is perhaps rather like that of an augmented reality display, in which a suitably

equipped user (courtesy of an eyeglass display, or, one day, retinal or even cortical implants) sees signs and information superimposed upon the actual visual scene in front of her eyes. Thus augmented, the user is able to distribute attention around the visual scene in new ways (for example, she might now follow a moving arrow traced in the sky and picking out a specific constellation of stars).

Experience with public language symbols, I want to suggest, augments human cognition in the same kind of way. It allows us to direct and distribute attention in new ways. And it does so by in effect creating a special kind of surrogate situation: one in which what is otherwise unavailable is not the visual scene itself, but a particular way of parsing the scene into salient components and events.

Further evidence in favor of such a view comes from the well-known studies by [5] in which two chimpanzees are presented with two bowls containing different numbers of pieces of fruit, and then one subject is asked to select the bowl the other chimp will receive. To get the most reward, the chimp must thus point at the bowl containing less fruit. Chimps are unable to do this. But when the same task is presented using numerals instead of fruit (numerals the chimps have, of course, been previously taught to understand!), they can succeed. Here, the use of the surrogate (numeral-choosing) situation apparently enables the chimp to inhibit an otherwise overwhelming response. This effect is not quite the same as the one in the tagging experiment, but it is similar in that here too, the use of labels frees the chimps from the gravitational pull of their ordinary perception-action routines. Contra Carruthers, then, I think we may conceive perceptually encountered or recalled symbols and sentences as acting less like inner data structures, replete with slots and apt for genuine inner combinatoric action, and

more like cheap ways of adding task simplifying and attention-reconfiguring structure to the perceptual scene.

Carruthers' assumption of wide-spread modularity and encapsulation is thus not needed. We can allow that human learning is sculpted by some innate biases, but we need not suppose that the thinkings thus supported are architecturally isolated from each other. Into this nexus, learning words (such as "blue") and phrases (such as "to the left of") may be seen as the developmental source of new forms of selective attention. Learning the words (which act as cheap behavioral targets for reward and reinforcement routines) shapes the child's attentional biases in language-specific ways that then promote new forms of problem-solving, such as the use of conjoint geometric and color cues. And certainly, there is ample evidence that children show attentional biases that are sensitive to the language they are learning (or have learnt)- for example, [4, 25, 34] explicitly suggests that learnt linguistic contexts come to "serve as cues that automatically control attention" (op cit p.113).

Carruthers might reply that this kind of story is undermined by the shadowing results in which linguistic activity in a distractor task impairs performance on (only) those tasks requiring integration of information across domains. But if the very process of selective attention to a complex conjoined cue required (in humans) the retrieval of at least some of the relevant lexical items, the shadowing result would equally be predicted. According to this alternative account, then, we need to first retrieve simple quasi-perceptual placeholders (such as words) when (and only when) a task requires us to target attentional resources on complex, "un-natural", or otherwise elusive, elements of the encountered scene. Such a picture is radically different from one such as Carruthers' in which the logical form of the natural language sentence provides the skeleton for a whole

new compositional internal representation unifying the outputs of multiple modules.

Words and sentences, on the view I am advocating, act as stable anchor points around which complex neural dynamics can then swirl and coalesce. Instead of thinking of linguistic encodings as enabling informational integration by acting as a common format for the outputs of multiple modules we can then think of the whole process as one not of translation into a single unifying representation but as one of *attention-based co-ordination*. Words and sentences here serve as kinds of simple, cheap quasi-perceptual marker posts, enabling the agent to attend to specific dimensions of a scene, including specific combinations of aspects of the scene, that would otherwise remain unnoticed. Language emerges as the source of a potent form of surrogate situatedness that makes available new ways of parsing a scene into salient, attendable, components and events.

5. Conclusions: Burrows within Burrows.

Our 'cognitive singing burrows' range from the use of simple tags and tokens, to the creation of mock-ups and models, on to the use of complex sentences and all the varied props and tools of the modern age. It is by means of this whole cascade of props and surrogacy that we humans routinely exceed the apparent limits of our basic modes of 'animal reason'. Yet while we may be amazed and impressed to learn that the humble mole cricket can use its earthbound burrows to form a double exponential horn set in a near-infinite baffle, and can thus amplify its humble stridulations into one of the loudest sounds in nature, we are routinely blind to the depth of our own cognitive transformations.

Consider: We do not just use our 'cognitive singing burrows' to think better. We use the burrows to help build better burrows. We build better tools to think with,

and use these very tools to discover still better tools to think with. And we tune the way we use our burrows, by building some burrows (educational practices) to train ourselves to use our best burrows better. Furthermore, we tune the way we tune the way we use our best burrows, by devising burrows to help build better burrows for educating ourselves in the use of our burrows (i.e. we devise tools for teacher education and training). Finally, unlike the mole cricket, we do not encode all the recipes for our burrow-building in our genes, not even as simple feedback-driven routines. Instead, we make the burrows themselves (books, oral traditions, software) do double-duty as their own encodings for production by future generations. We store in books and manuals the procedures needed to build paper-factories and book-binders, as well as the procedures to build planes, trains and automobiles.

Who we are, as human engines of thought and reason, is thus a matter densely determined by a cascade of 'extended cognitive physiologies' achieved by progressively fitting an open-ended sequence of technologies to somewhat plastic human brains. Just as in the case of the mole cricket, the special genetic program for all this may be surprisingly minimal. But once it is up and running, we are barely, if at all, constrained by the limits of the on-board apparatus that once fitted us to the good old Savannah (for lots more on this, see [11].

Scaling up new embodied approaches to confront the full gamut of human cognition thus requires a modestly brave step. It requires us to take our technological and cultural props and scaffolds seriously, and to treat these larger systems as the source of extended, and perhaps radically innovative, distributed cognitive architectures. That means developing a science of the mind, that although embodied and embedded, reaches far beyond the flesh.
